Abstract

Please use `\abstract{...}` to define an abstract in the document preamble.

Chapter **1**

Introduction

With the help of single-molecule fluorescence detection methods, optical studies have made many breakthroughs in the field of physics. Single-molecule fluorescence resonance energy transfer (FRET) is one of the most generally accepted techniques. Different kinds of kinetics of proteins, such as redox switching [1], have been revealed. This switching can be achieved either chemically or electrochemically. Previously, this switching was monitored chemically by adjusting the concentration of oxidizing or reducing agents. In this thesis a new setup is built and tested to achieve switching of proteins electrochemically. Instead of adjusting the concentration of oxidizing or reducing agent a potentiostat will change the potential. This allows more precise and faster changing potentials. With the help of this setup the midpoint potential of blue copper azurin (CuAz) labeled with ATTO 655 (position K122) and other kinetics has been determined.

This thesis does not only show the results of the new setup, but also shows some insights into how the setup was built. Not only does it describe the steps that did work, but also some of the steps that were not successful.

Chapter 2

Theory

In this chapter we explain the fundamental physics and electrochemistry which are used in the set up.

2.1 Fluorescence

Fluorescence is the property of certain molecules to absorb light at particular wavelengths and emit light at longer wavelengths. These type of molecules are called fluorophores or fluorescent dyes. A brief interval after absorption - the fluorescence lifetime - the atoms or molecules will emit light of less energy (longer wavelengths). Fluorescence is a process governed by three events. All these events occur on different timescales separated by several orders of magnitude. These events are summarized in Figure 2.1.

2.1.1 Excitation

The first event is excitation. For any molecule, several electronic states exist depending on the total electron energy and the symmetry of the electron spin states. Each state is divided in sub-states - a number of vibrational energy levels associated with the atomic nuclei. At room temperature, most molecules lack the internal energy to exist in any other state than the lowest vibrational level of the ground state. This ground state is usually an electronic singlet in which all electrons are spin-paired (opposite spins). With the help of a laser, photons with energy $E_{photon} = h\nu_{laser}$ are absorbed by the fluorophores. The absorption of energy happens to any of the closely spaced vibrational energy levels of the excited states.

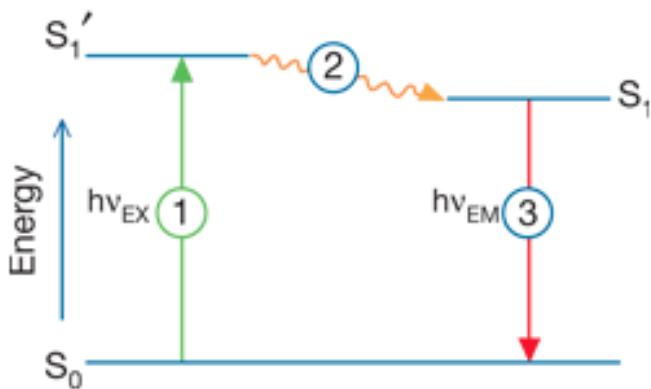

Figure 2.1: The three major events in fluorescence: excitation (1), relaxation (2) and emission (3).

Absorption of light occurs in a few femtoseconds ($10^{-15}s$). It will only occur for specific wavelengths known as the absorption bands. If a photon contains more energy than necessary for an electronic transition, the excess energy is converted into vibrational energy via non-radiative processes. If the energy of a photon is too low, no transition occurs. Excitation of a molecule by absorption normally happens without a change in electron spin-pairing. Therefore, the excited state is also a singlet. Usually the fluorophores are excited to higher vibrational levels of the first or second singlet electronic energy state. Certain transitions have higher probability than others and combined they form an absorption spectrum of the molecule.

2.1.2 Vibrational relaxation

After absorption, several processes occur with varying probabilities. The most likely is relaxation to the lowest vibrational energy level of the first excited state, a process known as internal conversion or vibrational relaxation. This is a loss of energy in a non-radiative manner and has a timescale of a picosecond ($10^{-12}s$) or less. Since a significant number of vibration cycles happen during the excited lifetimes, molecules undergo complete vibrational relaxation. The excess vibrational energy is converted into heat, which is transferred to the neighboring solvent molecules.

2.1.3 Emission

The excited molecule exists in the lowest excited singlet state for a period in the order of nanoseconds (10^{-9} s) before relaxing to the ground state. During this relaxation, a photon can be emitted. Because the ground state consists of closely spaced vibrational energy levels, the resulting emission intensity is distributed over a band of wavelengths rather than a sharp line. Most fluorophores can repeat the excitation and emission cycle a lot of times. However, the excited state is more reactive with the surrounding which can result in photobleaching: the molecule is permanently unable to fluoresce.

Other relaxation pathways compete with the fluorescene emission process. The excited state energy can be dissipated as heat, the excited molecule can collide with another molecule to transfer energy (for example quenching) or intersystem crossing to the lowest excited triplet state can occur. The latter will result in emission of a photon through phosphorescence or a transition back to the excited singlet state that yields delayed fluorescence. Molecules which exhibit the triplet state have a high degree of chemical reactivity, one of the covalent bonds in the molecule may be cleaved by reactions with surrounding molecules resulting in the photo bleaching of the fluorophore.

2.2 Fluorescence Resonance Energy Transfer

Fluorescence resonance energy transfer (FRET) permits determination of the position of two molecules within several nanometers distance, similar to the distance where molecular interactions occur. The process of resonance energy transfer can take place when the donor fluorophore in an electronically excited state transfers its excitation energy to a nearby chromophore (the acceptor). If the fluorescence emission spectrum of the donor molecule overlaps the absorption spectrum of the acceptor molecule and the two are within a minimal spatial radius, the donor can transfer its excitation energy in a non-radiative fashion through dipole-dipole intermolecular coupling. Treating an excited fluorophore as an oscillating dipole, it can exchange energy with a second dipole having a similar resonance frequency. If the acceptor itself is a fluorochrome, increased or sensitised fluorescence emission is observed. By exciting the donor and acceptor molecules with light of wavelengths centred near the absorption maximum of the donor, the detected light will be emitted at wavelengths centred near the emission maximum of the acceptor if FRET has taken

place. This resonance energy transfer is not sensitive to the surroundings of a fluorophore. The FRET efficiency is given by:

$$E = \frac{1}{1 + (r/R_0)^6} \quad (2.1)$$

where r is the distance between the donor and acceptor molecule and R_0 is the Förster distance - the distance at which the energy transfer efficiency is 50%. Related to this efficiency is the lifetime (τ'_D in presence of an acceptor and τ_D with the absence of an acceptor) and the fluorescence intensity (F'_D in presence of an acceptor and F_D with the absence of an acceptor) via the formulas

$$E = 1 - \frac{\tau'_D}{\tau_D} \quad (2.2)$$

and

$$E = 1 - \frac{F'_D}{F_D}. \quad (2.3)$$

2.3 FluRedox principles and labelled azurin

In contrast to FRET, FluRedox is based on the change of the overlap integral associated with a change in the optical properties of the redox-active centre upon oxidation and reduction. The optical read-out responds exclusively to the redox state of the protein [1].

Azurin is a blue copper protein with an active copper site (see Figure 2.2). The active centre of azurin has strong characteristic features in its optical absorption spectrum which is dependent on the redox state. It may occur in oxidised (Cu^{2+}) or reduced (Cu^+) form. Oxidised azurin exhibits a strong absorption band around 600 nm (blue). Fluorescent labelling of this protein makes it suitable for single molecule studies. ATTO 655 is a fluorescent dye with an emission band around 680 nm. The emission band of the dye and the absorption band of the azurin overlap (see Figure 2.3). When azurin is oxidised, FRET between the dye and the centre quenches the dye fluorescence. This quenching is absent when the protein is in reduced state because its 600 nm absorption has vanished [2].

2.4 Single molecules techniques

It is impossible to open newspapers without stumbling over words that reflect the impact of the life sciences in the modern world. Many specula-

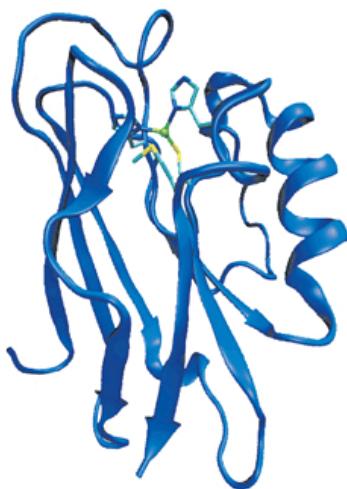

Figure 2.2: Three dimensional structure of azurin. The green sphere is the copper centre of the protein. Picture is taken from [3].

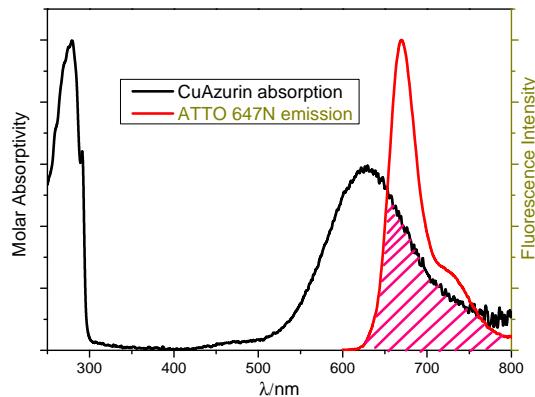

Figure 2.3: Absorption spectrum of CuAz (black) and the emission spectrum of the fluorescence dye ATTO 655 (red). The overlapping parts are purple marked. The absorption band around 600 nm is absent when azurin is reduced.

tions and discussions suffer from vagueness since many biological mechanisms are barely known to exist and even less mechanisms are fully understood. New and more precise techniques have made this field grow quickly. With new synthetic fluorophores, the ability to study single proteins at a time is exploited to investigate a variety of dynamics. One of the ways to get a better understanding of these single proteins is the usage of fluorescence correlation spectroscopy and the usage of confocal micro-

scopes.

2.4.1 Fluorescence Correlation Spectroscopy

The instrumentation of Fluorescence Correlation Spectroscopy (FCS) is based on an inverted confocal microscope. A laser beam is directed into a microscope objective via dichroic mirrors and focused on the sample. High numerical apertures are used. Fluorescence light from the sample is collected and passed through the dichroic and emission filters. A pinhole in the image plane blocks the light not originating from the focal region. When concentrations in order of a few - or less - nanomolar of fluorescent particles are applied, single particles can be monitored at a given time. A more detailed description can be found in reference [4].

The fluorescence intensity collected during the experiments were elaborated using the normalized autocorrelation (AC) function, defined by:

$$G'(\tau) = \frac{\langle I(t)I(t + \tau) \rangle}{\langle I(t) \rangle^2}. \quad (2.4)$$

Substracting the normal offset of value 1, this leads to

$$G(\tau) = G'(\tau) - 1 = \frac{\langle \delta I(t)\delta I(t + \tau) \rangle}{\langle I(t) \rangle^2} \quad (2.5)$$

where the brackets denotes temporal averaging and $\delta I(t) = I(t) - \langle I(t) \rangle$. The autocorrelation function is the correlation between a signal and the by τ delayed copy of itself.

2.4.2 Confocal Laser Scanning Microscopy

A Confocal Laser Scanning Microscope (CLSM) is the apparatus we used in this experiment. The CLSM is used to scan a sample. The sample is mounted on a moving piezoelectric scanning stage. This allows sub-micrometer movements. The scanning stage is moved along the confocal volume and the fluorescent signal is collected for each position sampled. Together with the fluorescence intensity, the setup is equipped to record the lifetime of the fluorescence and timetraces with the help of a time-correlated single-photon counting (TCSPC) board. A more detailed description of the setup is found in sections 3 and 4.

For this thesis, the Cu-azurin (CuAz) and Zn-azurin (ZnAz) were labeled and immobilized on the sample slide. Surrounded by an electron

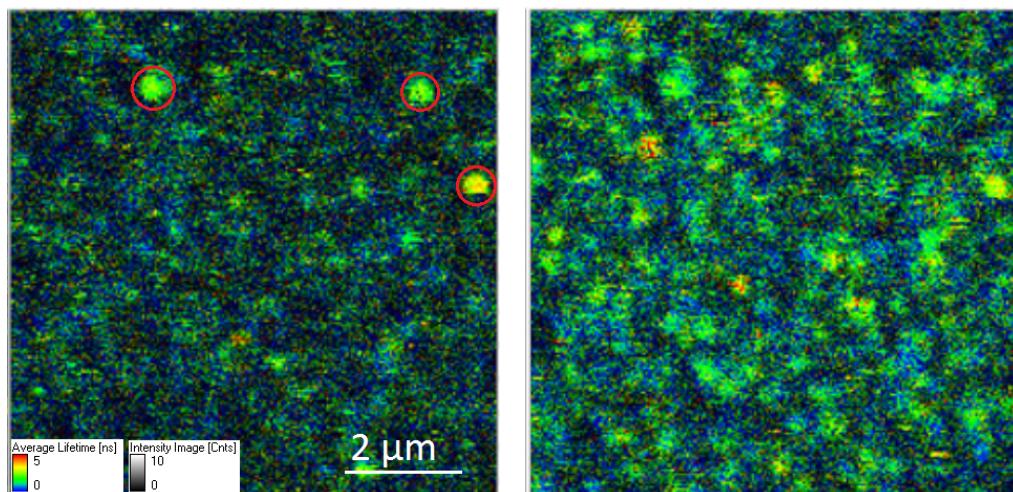

Figure 2.4: A $(10 \times 10) \mu\text{m}^2$ area filled with immobilized Cu-azurin at different potentials. On the right: potential of -100 mV , here the Cu-azurin is reduced (bright state). On the left: potential of $+100 \text{ mV}$. The Cu-azurin is oxidised and in the dark state. The bright spots (red circles) are either bleached proteins or impurities. A way to get rid of these impurities is by focussing the laser with slightly more power on these spots. On the right: same area, but with -100 mV potential. All the proteins are reduced. Comparing these two pictures immediately shows the active proteins and the non active proteins/impurities.

mediator, different potentials were applied on areas of $(10 \times 10) \mu\text{m}^2$, which have around 30 - 40 immobilized proteins. Initially applying a positive and negative potential, by analysing the fluorescence lifetime and fluorescence intensity, the active CuAz and inactive CuAz/impurities can be identified immediately after taking the images. Since the redox state affects directly the fluorescence lifetime and fluorescence intensity of the dye (see Figure 2.4), active CuAz is in the dark state when oxidized and in the bright state when reduced. Inactive CuAz/impurities are usually in bright state, independently of the redox state of the surrounding solution. Once we select the active proteins, the signal of the proteins is recorded for different time intervals (usually 30 seconds) resulting in timetraces as shown in Figure 2.5.

2.5 Binding protein to the surface

In a variety of different applications, such as detection systems, the biotin-avidin system has been used [5]. Living organisms develop highly specific

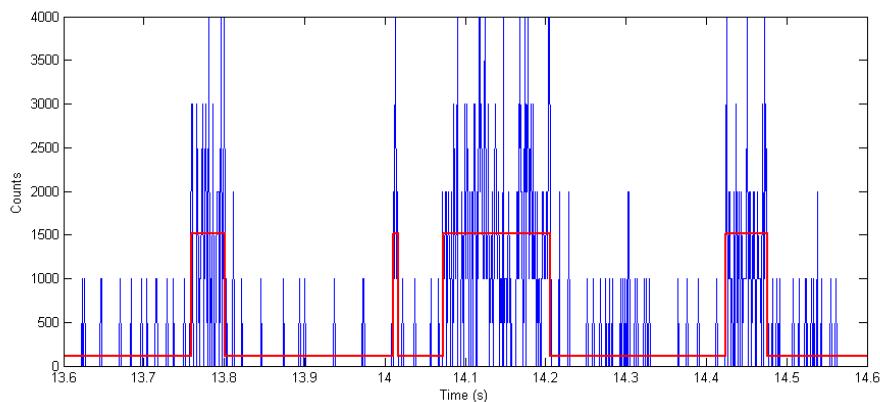

Figure 2.5: Example of a small part of a 30 sec timetrace of an immobilised Cu-Azurin in a -100 mV potential, taken with a CLSM. The blue line is the raw data, the red line is the fitted on and off magnitude and changepoint times. This is calculated using a specific program which is in more details described in the Data section.

defence mechanisms to help survive in unfriendly environments. Avidin, a protein found in egg white, has the ability to bind with very high affinity to vitamin biotin. This interaction is thought to represent a natural defence mechanism: the binding of avidin with biotinylated enzymes inactivates the enzymes that participate in CO_2 transfer and thus inhibits the growth of bacteria. Compared to other ligand-binder interactions, biotin-avidin has unique characteristics. The nonconvalent interaction of avidin with biotin has a formation constant of $10^{15} \text{ L} \cdot \text{mol}^{-1}$, much greater than the interaction of ligands with their specific antibodies (about $10^3 - 10^6$ times greater). On top of that, the avidin possesses four binding sites per molecule.

The NeutrAvidin is used unlabelled and serves as a link between the biotinylated binder (the biotin on the glass slide) and the biotinylated molecule (labeled Cu-azurin). This is illustrated in Figure 2.6

2.6 Oxidation-reduction reactions

Electron transfer (ET) is the exchange of electrons between molecules and can be generated by movements of electrons from one molecule to another in an oxidation-reduction (redox) reaction. Oxidation is the loss of electrons, reduction is the acquisition of electrons. The species being oxidized is called the reductant and the species being reduced is called the

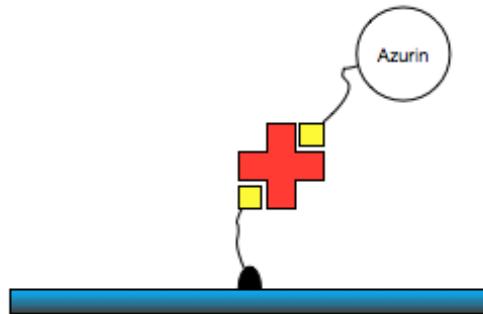

Figure 2.6: Illustration of the sample slide - NeutrAvidin - protein binding. The red cross is the NeutrAvidin, with the four corners representing the binding spots for biotin. The yellow squares represent the biotin. One side is bound to the glass surface while the other side is connected to the azurin

oxidant. The oxidation-reduction reaction can occur spontaneously. The two molecules participating in the electron transfer form a so called redox couple. The tendency to give or accept electrons is quantified by the midpoint potential which is generally measured with reference to the standard hydrogen electrode (SHE). The greater the midpoint potential difference between the redox couple, the greater is the driving force of the electrons. When a solution contains a mixture of reductants and oxidants, the solution potential can be given by the Nernst equation:

$$E = E^0 - \frac{RT}{nF} \ln Q \quad (2.6)$$

or in terms of \log_{10}

$$E = E^0 - \frac{0.0592}{n} \log_{10} Q \quad (2.7)$$

where Q is the reaction quotient and E^0 the midpoint potential. For a reversible reaction (which is usually the case in redox reactions)

where a, b, c and d are the stoichiometric coefficients for the balanced reaction, we can calculate the reaction quotient using:

$$Q = \frac{[C]^c [D]^d}{[A]^a [B]^b}. \quad (2.9)$$

When the reaction is in equilibrium, the reaction quotient Q is constant and equal to the equilibrium constant K . The equilibrium constant is related to the Gibbs free energy change of the reaction via the equation

$$\Delta G = nF\Delta E. \quad (2.10)$$

2.7 Electrochemical detection

Electrochemical detection instruments can be used for monitoring the current passing through a flow cell in liquid electrochemistry and flow injection analysis, but they can also be used for other electroanalytical applications. The potential control range of these instruments is $\pm 10V$. To reach certain potentials, a constant potential is applied and the current is recorded as a function of time (amperometric i - t curve), as is shown in Figure 2.7. Once the current in the i - t Curve is constant (i.e the curve is flat), the solution has reached the demanded potential.

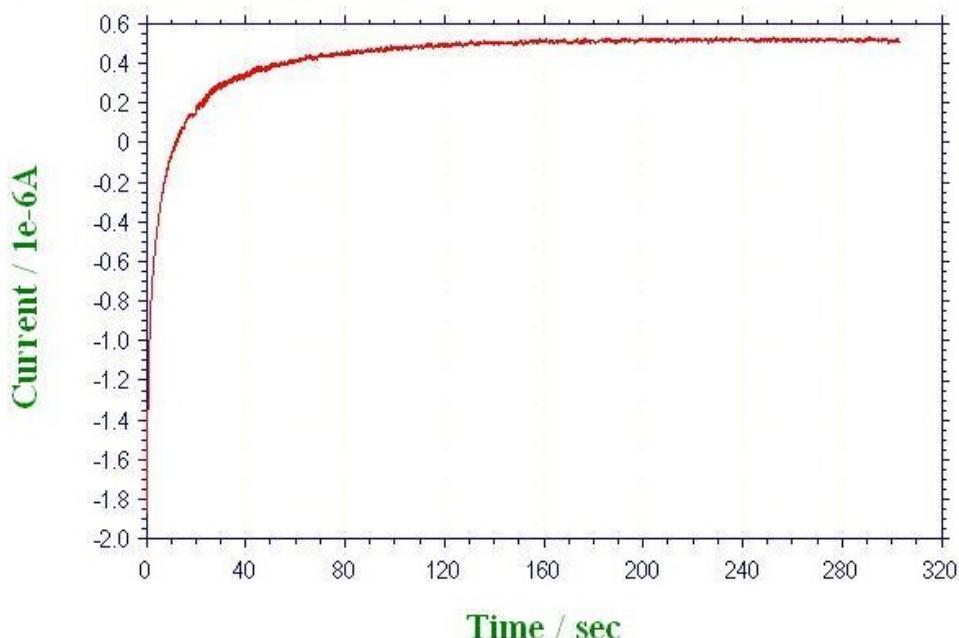

Figure 2.7: The amperometric i - t of oxidizing conditions (100mV). The curve goes flat within minutes allowing a change in potential in relatively short times.

Chapter **3**

Experimental setup

This chapter covers the building of the setup from the start till the end. In papers and publications, it is not common to describe how the experiment was built from the start till the end, but considered the duration and effort it took during this project it cannot be excluded from this thesis. The chapter is divided into three parts: the first part describes the setup in which the potential was tuned chemically by increasing or decreasing the concentration of electron donor. This was the setup that was used previously to perform similar experiments with single molecules. The second part of this chapter covers the establishment of the electrochemically setup. The final part of this chapter discusses this setup and how it operates. It is this setup with which the data were acquired.

Some parts and techniques such as the confocal microscope and functionalizing of the glass slides are used in both setups. Therefore these are described below.

In this chapter and the rest of the thesis, the blue copper azurin used in the experiments is labeled with ATTO 655 at binding site K122 (lysine at position 122). When copper azurin (CuAz) is mentioned, it is referred to the one with ATTO 655 label. The potentials measured and mentioned in this thesis are always with respect to the calomel electrode and have a pH = 7.4 (unless otherwise specified).

Confocal microscope

The experiments were performed on a home-built confocal microscope used for similar experiments. A 639 nm pulsed laser, controlled by a PDL 800-B (PicoQuant) laser driver at 40 MHz repetition rate, was passed

through a narrow band clean-up filter (LD01-640/8-25, Semrock). To collimate the beam to the desired diameter an aspheric lens of suitable focal length was used. The beam then got reflected via a dichroic mirror (ZT640RDC, Chroma) to the high numerical aperture (NA) oil immersion objective (1.4 NA, 100X oil, Zeiss). The stage on which the sample was mounted was controlled by a nanopositioning piezo element (P517.3CD, Physik Instrumente). The emission was collected and filtered through an emission filter (ET655LP, Chroma) and focused onto a 50 μm pinhole to remove background. Once the beam got focused on the active area of a single-photon counting module (SPCM-AQR-14, Perkin Elmer) data acquisition was performed by a photon counting PC-board (TimeHarp 200 PicoQuant). A schematic setup is shown in Figure 3.1.

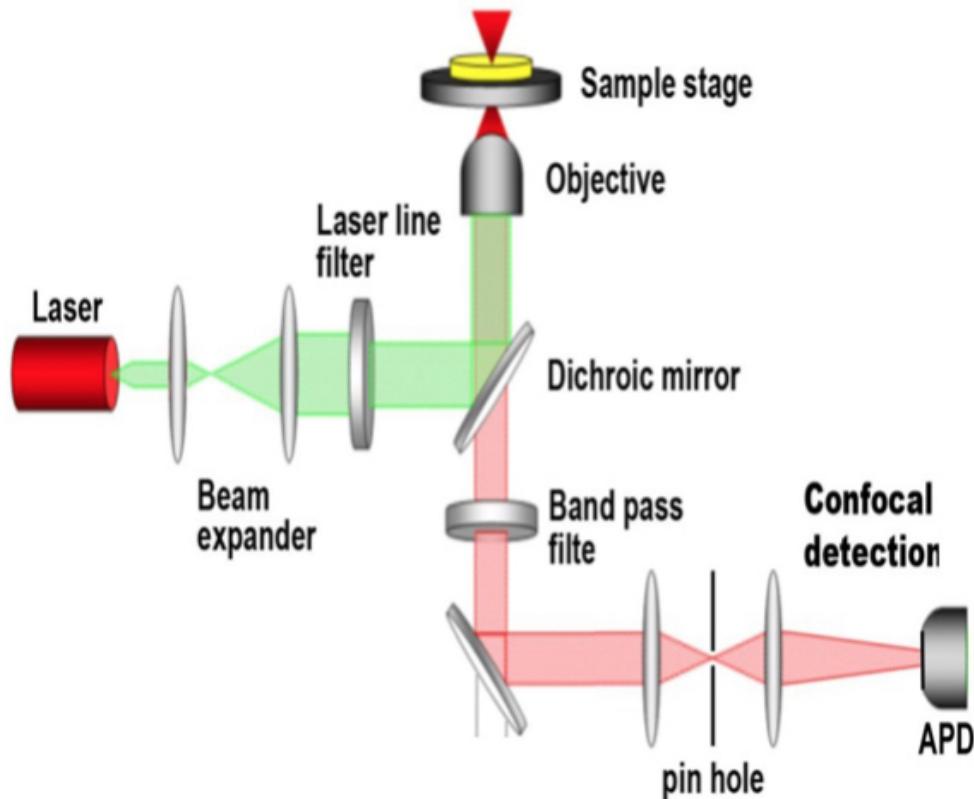

Figure 3.1: Schematic drawing of the confocal microscope used in the chemical and electrochemical set up.

Functionalizing glass slides

The functionalization of the cover glass is based on the process used in similar experiments with immobilised molecules [6][7][8][9]. Ø25mm #1 thickness glass coverslips (Menzel-Glaser) were used for all immobilizations. The coverslips were rinsed several times with milliQ water and treated with a H₂O/NH₄OH/H₂O₂ (5:1:1) bath at 70° C. The coverslips were then rinsed again but with water and finally with ethanol. As a result of this process, the coverslips contain active hydroxyl groups. Before usage, the coverslips were flamed and then ozone-cleaned for 15 minutes. Then the coverslips were treated for 30 min with a 1% solution of [3-(2-aminoethyl)aminopropyl]trimethoxysilane in methanol containing 5% glacial acetic acid. This results in the binding of the active hydroxyl groups to the [3-(2-aminoethyl)aminopropyl]trimethoxysilane (step 1 in Figure 3.2). The silane is not yet covalently bound. This is obtained by removing the layer of water which stabilizes the interaction of silane with the hydrogen bonds. The water is removed by baking the coverslips in an oven at 65° C for 3 hours. After this treatment, the cover slips were sonicated for 10 minutes and washed with methanol. Dried with clean nitrogen, they were left in the desiccator overnight. The next day they were treated with a mixture of 5 mg/mL methoxy-peg-N-hydroxysuccinimide (MW 2000, Laysan Bio) and 0.05 mg/mL biotin-peg-N-hydroxysuccinimide (MW 3400, Laysan Bio) in 50 mM phosphate buffered saline (PBS) with pH 7.4 (step 2 in Figure 3.2). This creates the surface of biotin and methoxy. The biotin then will bind to the NeutrAvidin with the CuAz attached to it (see section 2.5).

3.1 **Changing the potential chemically**

A small glass slide is functionalized in a similar way as explained in section 3. A syringe is used to suck solution through the tubes in a small cell onto the glass slide. One side is connected to the syringe, the other side is connected to the desired solution. First a solution of CuAz, NeutrAvidin and HEPES (pH = 7, 20mM) is put on the glass slide. After sufficient time, the CuAz will bind to the glass slide and the unbound CuAz will be removed by washing the slide with HEPES (pH = 7). Once the unbound proteins are removed, a new mixture containing 20mM ascorbate (C₆H₈O₆) and 20mM potassium ferricyanide ([Fe(CN)₆]⁴⁻) is incubated into the flow cell. Ascorbate is an antioxidant and exists predominantly as the ascorbate monoanion AscH⁻. The standard potential of ascorbate is around 40 mV (pH = 7) [10] with respect to a calomel electrode, which

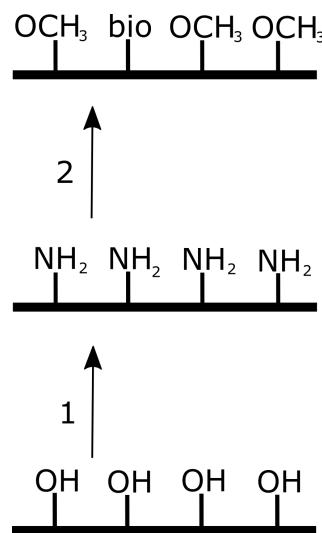

Figure 3.2: Steps of the functionalizing of the glass coverslips. The active hydroxyl groups react with the [3-(2-aminoethyl)aminopropyl]trimethoxysilane resulting in hydrogen bonds (step 1). The N-hydroxysuccinimide (NHS) of the biotin/methoxy-peg-NHS mixture binds with the amino (step 2). The result is a surface with a 1:100 ratio of biotin to methoxy.

is close to the standard potential of CuAz. Oxidation of ascorbate forms ascorbyl radical $\text{Asc}^{\bullet-}$, the equivalent of ascorbate but with one less proton and one less electron. Upon further oxidation this becomes dehydroascorbate ($\text{C}_6\text{H}_6\text{O}_6$) [11]. This is schematically shown in Figure 3.3.

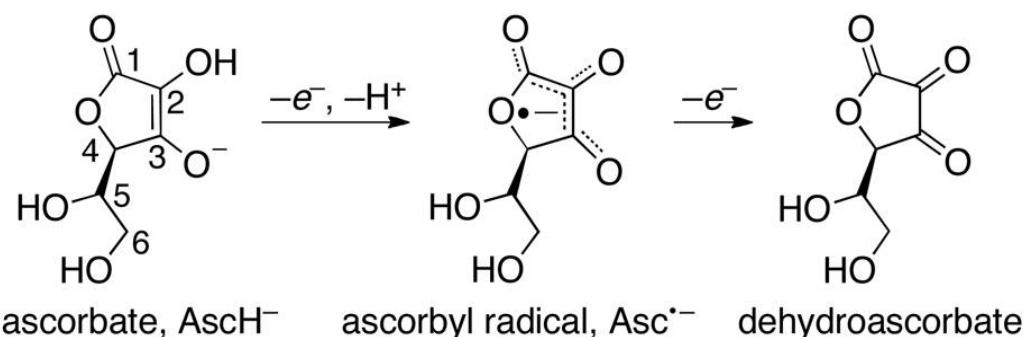

Figure 3.3: Redox of ascorbate

At equilibrium, using the Nernst equation (Formula 2.6), the potential can be written as

$$E = E^0 - \frac{RT}{nF} \ln \frac{[\text{C}_6\text{H}_6\text{O}_6][\text{Fe}(\text{CN})_6]^{3-}}{[\text{C}_6\text{H}_8\text{O}_6][\text{Fe}(\text{CN})_6]^{4-}}. \quad (3.1)$$

Thus by adjusting the concentration of ascorbate (in this case adding ascorbate) or ferri-/ferrocyanide, different potentials will be achieved in the solution. The final redox potentials of the solution were measured with a reference electrode (standard calomel, SCE) and a platinum counter electrode connected to a voltmeter.

Some of the downsides to this setup are listed below:

- The change of potential is induced by adjusting the concentration of ascorbate or ferri/ferrocyanide. By adding or removing substances, the solution will be disturbed. The chance of losing the monitored proteins is substantial if this is not done carefully.
- Reaching specific potentials is only possible by adding or removing the exact amount of redox participants. A small mistake and the wanted potential will not be reached.

These downsides lead ultimately to the desire of a better controllable and reliable setup.

3.2 Process to the final setup

In the previous setup the potential was controlled by adding different amounts of chemicals. In the electrochemical setup, these changes are achieved electrochemically. Beside the confocal microscope, a new instrument has to be introduced: the electrochemical analyzer or potentiostat (Model 800B Series Electrochemical Detector, CH Instruments). Instead of using different concentrations of ascorbate, a cell with a working electrode, counter electrode and reference electrode in a buffer are used. During the process of getting to the final setup, the same working electrode, counter electrode and reference electrode is used: a $\varnothing 0.25$ mm gold wire acts as the working electrode, the counter electrode is a $\varnothing 0.5$ mm thin platinum wire and the reference electrode is a saturated calomel electrode. All the potentials throughout this work are reported relative to the SCE.

3.2.1 Electron mediator

When looking at single-molecule level, it is expected to see the molecule spend half the time reduced and half of the time oxidized when the potential is set to the mid-point potential of the molecule. This is evidenced by equal on- and off-times for the blinking. For reducing potentials the molecule will spend more time in the off state and for oxidizing potentials

the molecule will spend more time in the on state. It is therefore important to have a range of potentials that are below and above the mid-point potential of the molecule of interest. In the case of Cu-azurin, the midpoint potential is around 25 mV. A solution consisting of a buffer and a redox-pair is needed to act as electron mediator to obtain the potentials around the mid-point potential of Cu-azurin. A good way to check what range of potentials such solution can reach is the use of cyclic voltammetry (CV). This is a plot of the current versus the potential. Since the previous setup did not use the potentiostat, the first thing we did for this experiment was using this device to obtain the CV of different solutions to find the one solution that suits this experiment the best.

To obtain the CV of different solutions, a small setup was made. A volume of around 200 mL was put on top of magnetic mixer and the working, reference and counter electrode were lowered into the solution and connected to the potentiostat. With this setup, three different solutions were chosen based on their midpoint potential (see below). It is useful to choose a solution with its midpoint potential close to the midpoint potential of the CuAz, since it is easier to reduce or oxidize near the midpoint potential. For obvious reasons, the interesting potentials in this thesis are the potentials around the midpoint potential of CuAz.

1. A solution with ascorbate. Ascorbate, together with ferricyanide, is used in the chemically-induced redox switching setup. The details of the redox of ascorbate are described in more detail in section 3.1.
2. With a midpoint potential of 6 mV, the redox couple potassium ferricyanide ($[\text{Fe}(\text{CN})_6]^{4-}$)/ferrocyanide ($[\text{Fe}(\text{CN})_6]^{3-}$) is a close to perfect candidate for this experiment. The oxidation of ferrocyanide, resulting in ferricyanide is given by

Following the Nernst equation:

$$E = E_{\text{FeCN}}^0 - \frac{RT}{F} \log_{10} \frac{[\text{Fe}(\text{CN})_6]^{3-}}{[\text{Fe}(\text{CN})_6]^{4-}} \quad (3.3)$$

3. The last solution tested was phenazine ethosulfate (PES), $\text{C}_{16}\text{H}_{18}\text{N}_2\text{SO}_4$. Its midpoint potential is 55 mV and very close to the documented midpoint potential of CuAz. PES in oxidized state may receive electrons from the electrode to get reduced and in closed vicinity the redox potential is controlled by the concentration ratio of $[\text{PES}]_{\text{ox}}/[\text{PES}]_{\text{red}}$.

In the final setup, the total volume of the solution is 4 mL. When trying to measure the potential of the ferri/ferro redox couple, a volume of 200-300 mL was used. While stirring, oxidizing the redox couple was a fast process. Reducing the ferricyanide, however, took much longer. One explanation could be oxygen. Water contains hydrogen in the oxidation state +1 and oxygen in the oxidation state -2. Because of that, the reaction

can occur [12]. This will slow down the production of Fe^{2+} and thus according to the Nernst equation, lower potentials will be reached slower or not at all. Also the setup is not sealed from the air which contains oxygen. In previous voltage-induced redox switching experiments[13] measurements in anaerobic conditions were performed to reduce (in some cases it was reduced so that the interaction with oxygen was considered non-existent) the interactions with oxygen. This problem occurred for the other solutions too, but for PES to a lesser extent. Therefore a 200 μM PES in PBS with a total volume of 4 mL was chosen as electron mediator in the following experiments.

3.2.2 Proteins on the surface

Having functionalized sample slides and a fitting electron mediator, the next phase in the process to the final setup is to get the right amount of proteins on the sample slide. As mentioned in section 2.5, NeutrAvidin is used as a link between the sample slide and the proteins and has four possible binding spots (Figure 3.4). Before the proteins were applied on the sample slide, they were mixed together with NeutrAvidin. Different ratios between proteins and NeutrAvidin were tried to find the right ratio. When the ratio between proteins and NeutrAvidin was 1:1, a shorter lifetime and lower intensity was observed for the immobilized proteins. When more than one azurin is attached to the same NeutrAvidin, each azurin acts as a quencher to the other when close enough to each other [14]. The excited dye on one azurin can couple to the dye on the other azurin, which is attached to the same NeutrAvidin, resulting in quenching: the protein returns to the ground state, without emission of a photon. This visualizes as blue spots on the sample slide as is shown in Figure 3.5. Lowering the ratio of proteins to the same amount of NeutrAvidin ensures the fact that less protein will bind to the same NeutrAvidin. At some point the probability that the NeutrAvidin is bound to more than one protein is very slim. This is the case when the ratio between protein and NeutrAvidin is 1:40 and this ratio is used in further experiments.

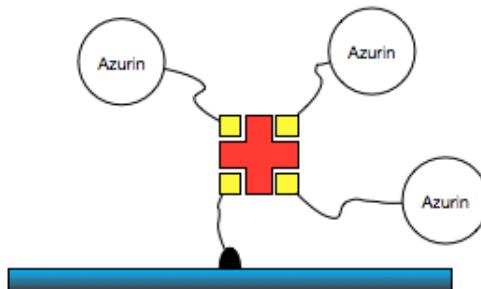

Figure 3.4: Illustration of NeutrAvidin (red cross) bound to three azurin molecules via biotin (yellow). This is likely the cause of self-quenching.

3.2.3 The working electrode

In an electrochemical system, the working electrode is the electrode of interest. In this case the working electrode is made of gold, since gold is one of the best electron conductors. The reaction of interest is occurring on and near the working electrode in conjunction with the counter electrode and reference electrode. Since the establishment of the redox potential relies on the diffusion of the electron mediator, the actual redox potential sensed by the molecule is dependent on the distance between the working electrode and the molecule as well as on the time after an external potential is applied. One way to keep the distance between the molecule and working electrode as small as possible is by creating a gold layer on top of the functionalized sample slides with the help a sputtering machine. This gold layer is in touch with the electrochemical analyzer via a $\varnothing 250$ mm gold wire. By creating transparent areas where proteins are immobilized such that the distance between the gold border and proteins is sufficient small and applying an external potential long enough, it can be assumed that the potential on the gold is equal to the one in the near surrounding. Using a 20 nm thin gold layer gave a lot of problems, however.

One of the problems to overcome was to find a proper way to create transparent areas in the gold. These areas need to meet some requirements such as a size (usually a cross section of several tens of micrometer) big enough to monitor multiple (20-30) proteins at the same time. Several different methods were tried (see Figure 3.6) and some of them are described hereafter.

1. **Scratches.** The first attempt was sputtering the whole glass slide with a 20 nm thin layer of gold. With a needle scratches were made

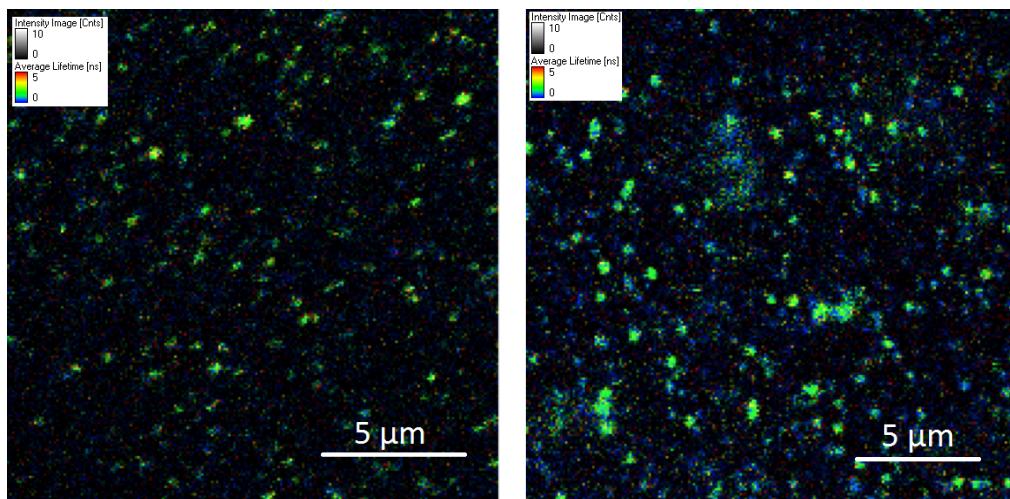

Figure 3.5: A $(20 \times 20) \mu\text{m}^2$ image of immobilised azurin on the sample slide with different ratios of protein to NeutrAvidin. Left: the ratio between protein and NeutrAvidin is 1:1. Right: the ratio between protein and NeutrAvidin is 1:5. When the amount of proteins to NeutrAvidin is decreased, a decreased amount of quenched proteins (blue spots) is observed.

and imaged. When making scratches it is of big importance to not cross other scratches. Once the scratches cross each other, areas of gold that are isolated from the gold layer that is in touch with the wire can be created. The gold will not be connected to the working electrode in that case and no electrochemical changes will be seen near those edges. Once the scratches were made and put under the microscope it was easy to locate the transparent areas. However, the transparent areas created in this way were often too small to monitor multiple proteins at once. Beside that, the functionalised sample slide happened to get damaged along this process: when making scratches it is difficult to apply the same pressure along the scratches resulting in different depth of scratches. The dimension of proteins are in the nanometers. Different depths make it impossible to focus on multiple proteins in the same area at once.

2. **Small pieces of glass.** To get areas with the same depth, small pieces of smashed glass were laid on top of the immobilised glass slide before sputtering with gold. Once the sputtering was finished, the pieces of glass were removed resulting in small transparent areas (see the left side of Figure 3.6). The borders between glass and gold were sharp (the borders were 'sharp' on the images), but again a lot

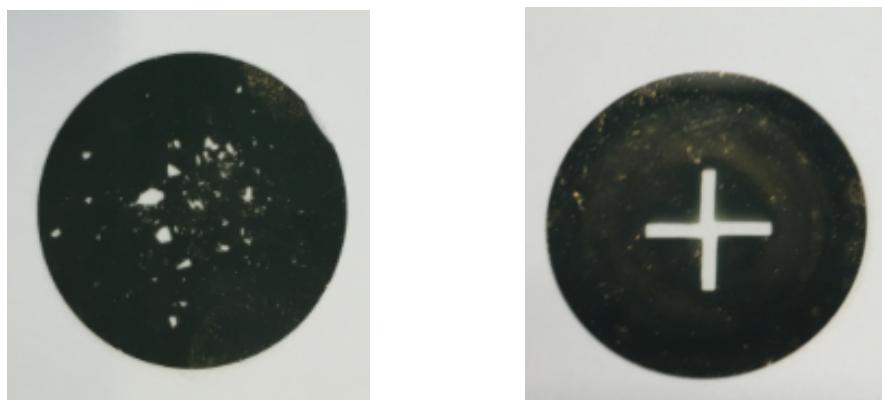

Figure 3.6: A few examples of the $\varnothing 25$ mm glass slides with a gold layer on top of it. Left: the transparent areas created with the help of small pieces of glass. Right: with the use of small iron crosses a cross-shaped transparent area was created.

of areas formed via this method were too small to monitor multiple proteins. Later it was done with only a few bigger pieces of glass to avoid these small areas. This showed some improvement.

3. **Metal crosses.** Small metal crosses on top of the glass before sputtering, resulting in cross-like transparent areas (see Figure 3.6). These transparent areas were easy to locate, the edges were straight and the borders were sharp as long as the gold layer was 30 nm thick, see Figure 3.7. If a certain $(80 \times 80) \mu\text{m}^2$ area didn't suit single protein experiments, it is easy to slide along the border to find an area that suits better.

The latter method to create reliable areas is used in the next phase of the experiment: the combination of the electron mediator, proteins and the gold layer. Individually these parts worked as intended. However, a combination of the parts led to two serious problems:

1. Damaged gold layer. The longer the experiment continued, the more clear it was that the border of the gold layer would slowly detach. At the end of a day of experiments, the gold layer was damaged to such an extent that it would simply detach from the sample slide. The PES is most likely the reason for this. Though the exact reason for this was never clear - when a gold layer was exposed to a different electron mediator (ferricyanide or ascorbate) the gold layer seemed to be not damaged. The damage caused by PES can be seen if you compare the border of the gold layer (bright blue) of Figure 3.8 (left) - taken at the start of the experiment - with the border of Figure 3.8

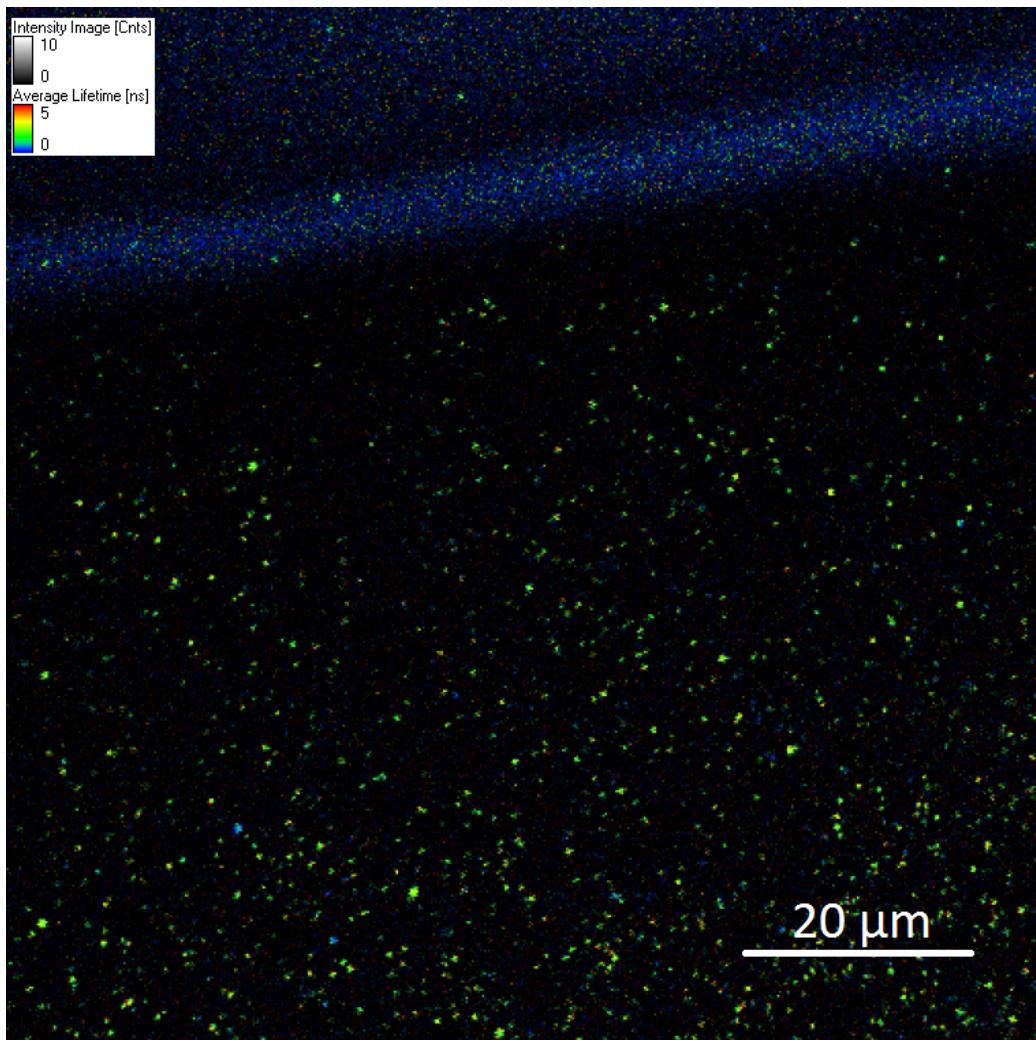

Figure 3.7: $(80 \times 80) \mu\text{m}^2$ image of the sharp border. The top part of the image is gold, the bright blue line is the border between the gold and the glass and the green spots below the border are azurin single molecules.

(right side, this picture was taken towards the end of a day of experiments). One way to tackle this problem would be a protective layer on top of the gold layer. This protective layer is 4-Mercaptobutanoic acid ($\text{C}_4\text{H}_8\text{O}_2\text{S}$). This kind of protective layer has been used in similar experiments [15] where it has been shown that the length of the carbon chain can vary without affecting the electron exchange between the gold and the single molecule. In these experiments, however, usually the molecules were on top of the gold layer whereas in our case the proteins are next to the gold layer. The result of using

this protective layer was that the proteins did not show any reaction to a change in potential. Since the protective layer did not work, the other way to tackle the damaged gold layer is an increase in thickness of the gold layer. This will not solve the problem, but delay it long enough to do proper experiments. In all previous experiments, the thickness of the gold layer was 20 nm. Increasing the thickness of the gold layer led to the second problem.

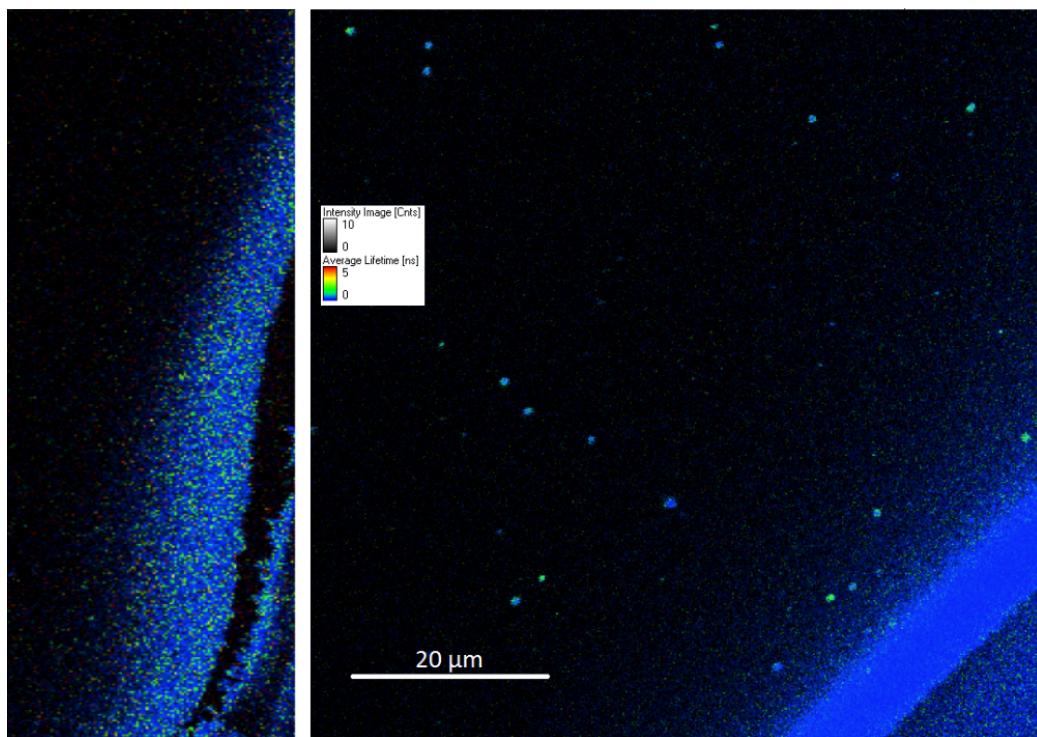

Figure 3.8: Left: part of an $(80 \times 80) \mu\text{m}^2$ area showing the fractured border due to PES damaging the gold layer. Right: the $(80 \times 80) \mu\text{m}^2$ of the glass surface near the 200 nm thick gold layer. As can be seen, almost no proteins are present despite using the same molecule density.

2. Missing proteins. Near the edges of the working electrode, a much lower density of proteins was observed (see Figure 3.8) once the gold layer thickness was increased. The reason for this could be that during the sputtering of the gold layer, the metal crosses would slightly move a little bit and thus damaging the methoxy-peg-NHS layer. This would make it harder for proteins to bind near the surface. Another explanation could be that some gold-atoms might have slipped under the metal cross and occupied the spots where the proteins usu-

ally would bind.

The final setup: platinum grid

At this point of the process it was clear that the gold-layer as a working electrode in the current setup gave too many problems and a different solution was attempted. Instead of using a gold layer, a single gold wire was kept on the sample slide to see if this would give any good results. This can be seen in Figure 3.9. The green color are the proteins showing switching and blinking. This was the first sign that instead of the gold layer, a (gold) wire on its own suited as a working electrode. Finding a single wire with the microscope and keeping it on the sample slide is a tough task and is not controllable and thus a change was needed. Instead of one gold wire, a platinum rectangular grid (the total length/width of the grid is around 2.5 cm) was used and pressed onto the sample slide with the help of a small glass slide. Not only is the pressure evenly applied on the grid when pressure is applied on the glass slide on top of the grid, but also small confined volumes are formed where the sample slide and glass slide form the 'floor' and 'roof' and the platinum grid the 'walls'. These confined volumes are in the order of nanoliters, which makes switching possible in a matter of minutes. On top of changing the working electrode, also the electron mediator was changed. Once the setup worked, PES showed more disadvantages such as its very high autofluorescence which makes the signal-to-noise ratio very low. PES is hydrophobic and is difficult to mix with the PBS: it will get stuck on the surface and interacts with the proteins. To avoid these problems a different electron mediator is used in the final experiments. A mixture of 200 μM ferricyanide and 100 μM ascorbate was mixed with PBS to a total volume of 4 mL. This was the last step in order to make the whole setup work as intended. The setup is schematically drawn in Figure 3.10 with a short description of its parts.

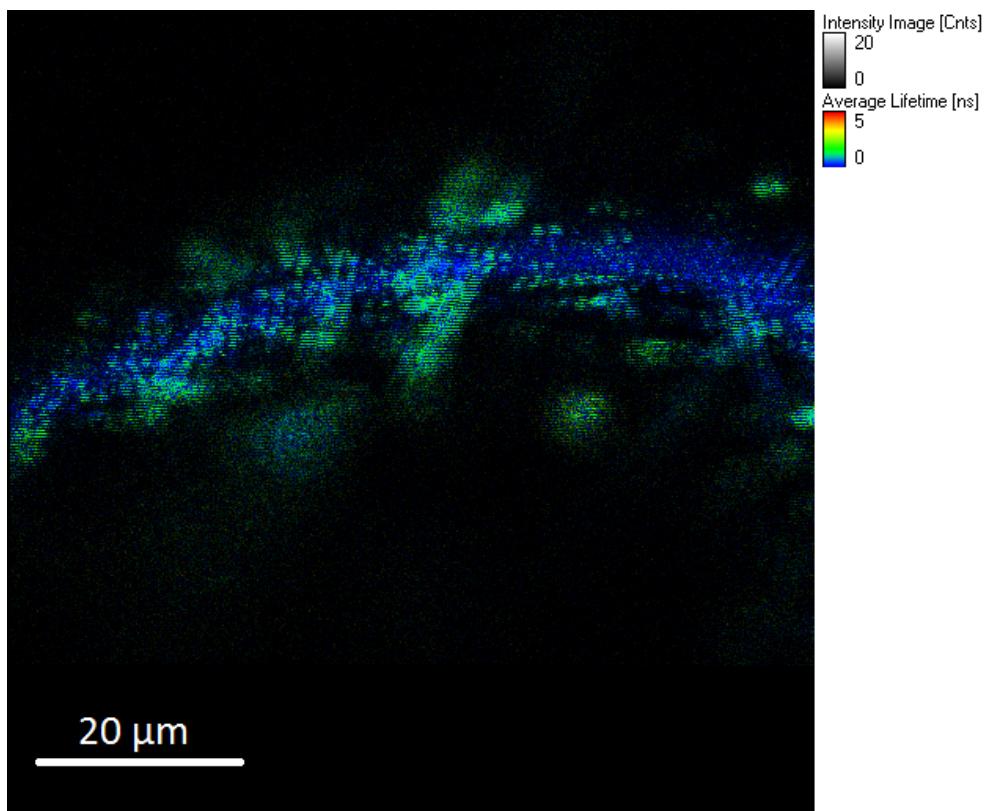

Figure 3.9: A $(80 \times 80) \mu\text{m}^2$ area of the sample slide with immobilized proteins. The blue 'snake' is the gold wire that touches the sample slide. The green spots represent the oxidized proteins. This is the first proof that proteins near the wire show oxidation.

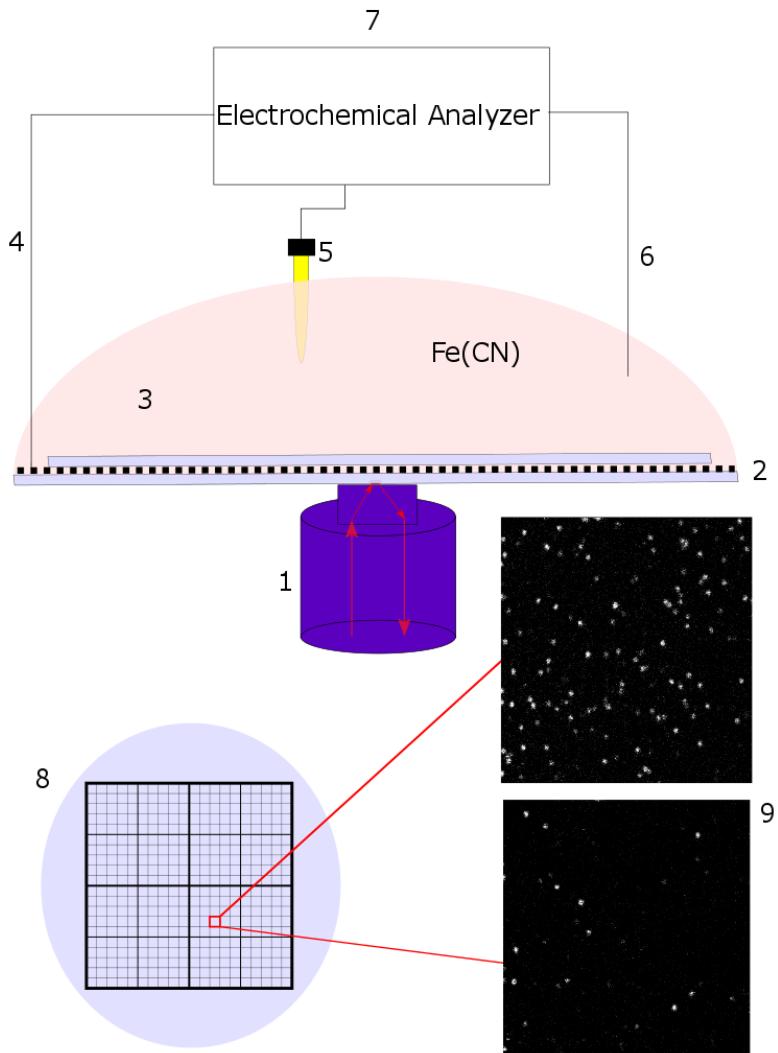

Figure 3.10: Not to scale schematic picture of the final setup in which the potential is changed electrically. (1) The confocal microscope as described at the beginning of this chapter. (2) The functionalized sample slide with on top the platinum grid and another small glass slide to press the grid on the sample slide, resulting in small confined volumes in the order of nanoliters. (3) The electron mediator consisting of 200 μM ferricyanide, 100 μM ascorbate and PBS (PH 7.4) with a total volume of 4 mL. (4) The working electrode (gold wire) in connection with the platinum grid (section 3.2.3). (5) The saturated calomel reference electrode. (6) A platinum wire, not touching the grid, as the counter electrode. (7) The electrochemical analyzer (Model 800B Series Electrochemical Detector, CH Instruments) to which the electrodes are connected. (8), (9) Top view of the sample slide and two pictures of the same area showing the same CuAz reduced and oxidized.

Results and discussion

The experiments were performed with the blue copper protein azurin from *Pseudomonas aeruginosa*, labeled with ATTO 655 (referred to as CuAz in the rest of the analysis). This small protein, with a molecular mass of 14 kDa, is involved in electron transfer (ET) reactions in a variety of both plants and bacteria. Its label, ATTO 655, has been chosen since its properties have been well documented [16]. The labeling site used in this experiment is K122 (lysine at position 122), one of the closest labeling sites to the copper center of CuAz. In the future one could label ATTO 655 to a labeling site further from the copper so that the copper-dye distance changes from less to greater than the Förster radius R_0 value for maximal sensitivity [17]. Beside the blue copper protein azurin, fluorescently labeled zinc azurin (ZnAz) was also used to perform control experiments. This wild-type protein is used as a control. Zinc azurin does not possess the ability to redox switch and is therefore an ideal control. When zinc azurin is exposed to different potentials, only the interactions between the dye and the solution appear. By subtracting this interaction of the dye and the solution of the timetraces of CuAz, only the interaction between the electron mediators and the copper centre will remain.

Data collection

The sample, mounted on the scanning stages, was brought into the focal plane of the objective. Once an area was chosen, images of $(80 \times 80) (\mu\text{m}^2)$ were recorded as x-y scans. A positive and negative potential is applied and captured to detect the redox switching CuAz. Images of typically $(20 \times 20) (\mu\text{m}^2)$ were recorded in which at least 10 redox switching molecules

were present. To collect data from a single molecule, the laser was parked on the blinking molecule and measurements were made for 30 seconds. Once all the blinking molecules of interest were measured, a new potential was applied and this process repeated. Many fluorophores bleach within minutes, thus only the timetraces of those molecules who survived at least four different potentials were included for further analysis.

To make sure that the surroundings of the single molecules were indeed at the intended potential, the I-t curves were recorded at the same time. Once the I-t curves stay constant, it is assumed that the solution has the same potential as the potentiostat applies. Two examples of these I-t curves are shown in Figure 4.1

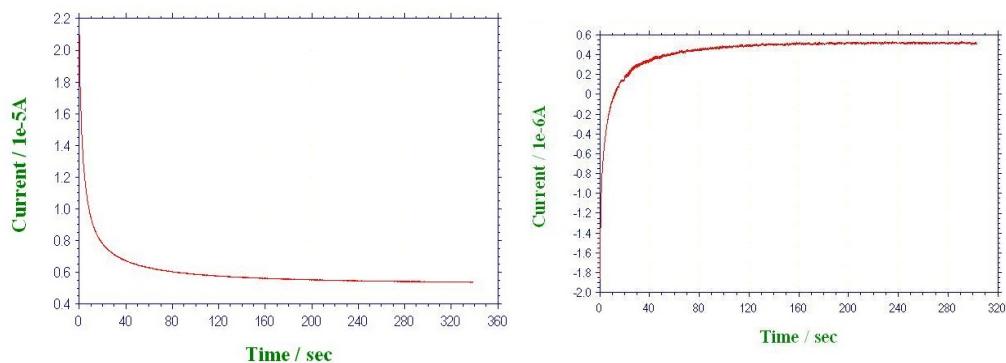

Figure 4.1: The amperometric I-t curve. Left: the I-t curve of reducing conditions (-25 mV applied in this case). Right: the I-t curve of oxidizing conditions (100 mV applied in this case).

Timetrace analysis

The software used for the fluorescence lifetime imaging and correlation software is SymPhoTime 64. With the help of this program, timetraces and their specific parameters are saved in .pt3 files. Older versions of SymPhoTime saved this data into .t3r files. Previous PhD student Dr. Ankur Gupta had written a program in MATLAB R2012b to read out the .t3r files and transfer the timetraces into multiple .dat files. This program has been adjusted in such a way that it can read out the .pt3 files from the newer version of SymPhoTime 64. It allows you to manually select parts of the timetrace, as is shown in Figure 4.2.

Once the timetrace is selected and put into several .dat files, another C program is run to precisely calculate the on- (τ_{on}) and off-times (τ_{off}). This

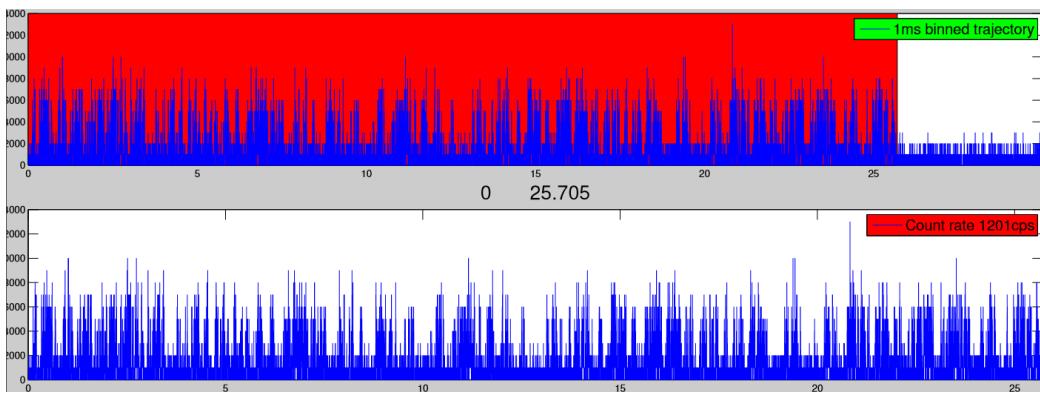

Figure 4.2: Selection of a timetrace with a program written in MATLAB R2012b and C to select the parts of the timetrace (in red) that will be put into .dat files. In this specific case the CuAz bleached at around 25.7 s. Once the CuAz is bleached, the remainder of the timetrace is not of interest and thus not selected.

program uses several mathematical methods to calculate the timestamps and intensity in optical single molecule emission data that exhibit discrete intensity jumps, in detail described by Lucas P. Watkins and Haw Yang in their paper [18]. As an example, several on- and off times are visualized in Figure 4.5. The on-time is defined as the time when the intensity is high, which is the case when CuAz is reduced. The off-time is when the intensity is low and the CuAz is oxidized. The program does not distinguish the cause of the intensity jumps. In this case there are two main reasons for intensity jumps. The first reason is intensity jumps that are related to the redox of the copper center. These intensity jumps are referred to as 'switching'. The second reason is related to the (often) unwanted and uncontrolled intensity change due to the interaction between the dye and the surrounding solution, and this is referred to as 'blinking'. To distinguish the on- and off-times for these potentials, the autocorrelation is used. This is explained in more detail in section 4.0.2.

4.0.1 Timetraces CuAz

Looking at the timetraces between 100 mV and 0 mV (Figure 4.6) a trend is noticeable on sight. For the higher potentials, the off-times (τ_{off}) are long and the on-times (τ_{on}) are relatively short which goes hand in hand with the low amount of events and the low average fluorescence level. When the potential decreases, the amount of events start to increase and the τ_{on} becomes longer while τ_{off} becomes shorter. The explanation for this is simply the FluRedox principle. CuAz in oxidized form (copper is

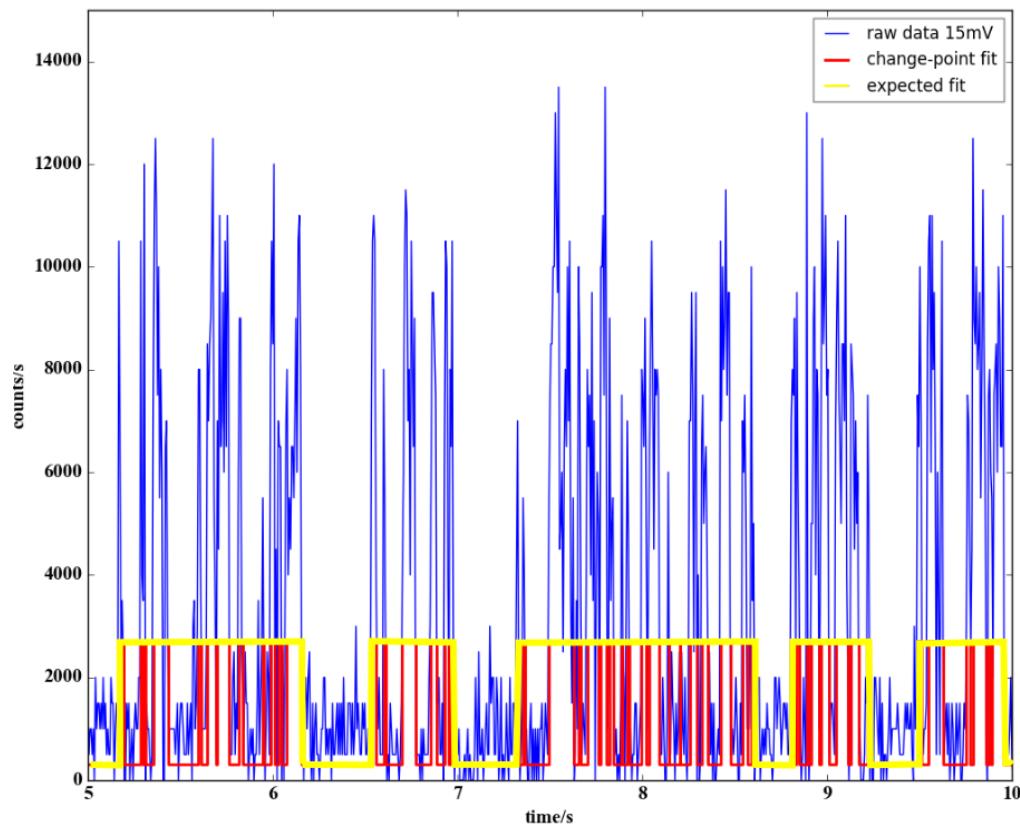

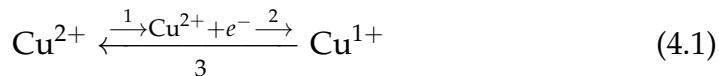

Figure 4.3: A timetrace of CuAz at 15 mV potential. The yellow fit shows the expected intensity jumps due to redox switching, while the red fit shows the observed intensity jumps. The very short on-times are related to the blinking of the dye due to interaction with the oxidized surrounding, while the yellow jumps represent the expected intensity jumps due to the switching of the CuAz.

in Cu^{2+}) shows an absorbance maximum around 628 nm which overlaps with the fluorescence emission of the ATTO 655 dye as is shown earlier in Figure 2.3. Since energy transfer is high in this form, the fluorescence of the dye is quenched resulting in longer τ_{off} . When the potential is decreasing, the solution is reducing. When CuAz is reduced - since the absorption at 628 nm disappears upon reduction - the energy transfer is low and thus the dye shows high fluorescence and longer τ_{on} times are expected. This mechanism seems to be the only one at work until the potential comes near 40 mV. Here a new phenomenon is noticeable. Beside the expected increasing τ_{on} and decreasing τ_{off} due to switching of CuAz, a secondary timescale seems to appear in the form of very short τ_{on} in very short succession. To explain this event, a closer look has to be taken at the chemicals

involved in the chemical processes concerning the redox reactions. Intermolecular reactions between the redox active components in the solution and the dye are present. For higher potentials, the timescale of the blinking events between dye and solution are long. When the potential gets lower, the solution is more and more reduced. The interaction between the dye and the reduced ascorbate and ferricyanide happens on a smaller timescale and is now prominent in the timetraces (see Figure 4.3). This is more apparent when looked at the autocorrelation.

Another way of looking at the on- and off-times acquired by the timetraces is by plotting the on- and off-times in histograms. This is done in Figure 4.4. The on-times follow a single-exponential distribution, but the off-times have a different form. Very short off-times seem to be relatively rare. The distributions of τ_{on} and τ_{off} should be both single exponential if the reduction and oxidation reactions are first order rate constants and involve only one rate constant. To get a deeper understanding of this a closer look has to be taken at the electron transfer process between the solution and the copper azurin.

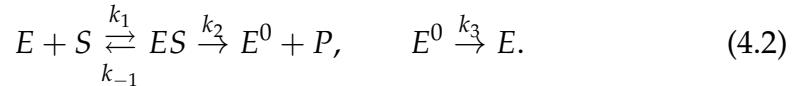

The reduction of Cu^{2+} to Cu^{1+} is a multi-step process if it is a predecessor-successor reaction. Bringing the electron close to the copper center (step 1) and reducing the copper (step 2) is happening in steps, characterized by specific rates. **Therefore the reduction of copper involves two rate constants.** These two steps result in the absence of the short off-times: reducing takes longer than oxidizing. The oxidation of the copper center is 'easier' since it involves the removal of an electron from the center and is a single step process. This is consistent with the distribution histogram of the on-times, which clearly shows the presence of the very short on-times.

Finally we will look at the correlation of the on- or off-times after one or more turnovers. This has been done previously by M. Orrit et al. [19], where a simple fourstate system - in case of a first-order reaction - is proposed consisting of two two-level blinking models. This model is very similar to the case of CuAz, where the fast blinking and slow switching dominate the timetraces. Furthermore they showed that slow fluctuations lead to strong memory effects and the scatter plots follow inverse diagonals. When memory is completely absent (a random slow or fast blinking event for each cycle), a high number of correlation points is found where a short time correlates to a long one and vice versa.

A analogue way to describe the activity of turnover events separated by periods of low activity is with the Michaelis-Menten equation. Accord-

ing to the Michaelis-Menten mechanism, a substrate S binds reversibly with enzyme E to form the complex ES :

Then ES produces P and E is regenerated for the next catalytic cycle. It has been proven that the Michaelis-Menten equation holds for single molecules according to the single-molecule Michaelis-Menten equation [20]:

$$\frac{1}{\langle \tau \rangle} = \frac{k_2[S]}{[S] + K_M}, \quad (4.3)$$

where K_M is the Michaelis constant. This process is similar to the redox of CuAz and though not done in this thesis, further research on this subject might reveal new insights on the characterization of the memory effects.

4.0.2 Autocorrelation CuAz

When the solution is reduced (at a potential of 40 mV or higher) the interaction between the dye and the solution is minimized. The intensity changes due to the blinking of the dye happen on a much bigger timescale than the redox switching and the on- and off-times calculated by the program are assumed to be due to the redox switching of the CuAz. When the potential is changed to values below 40 mV the interaction between the dye and the solution becomes more prominent (shorter timescale) in the timetraces. An example is shown in Figure 4.3. Instead of one on- and off-time for the redox, a new on- and off-time due to the blinking of the dye is present. A way to distinguish which on- and off-time belong to the redox switching and which on- and off-time belong to the blinking of the dye is with the help of the autocorrelation. At higher potentials the autocorrelation can be fitted with a single exponential in the form of

$$g(\tau) = A + Be^{-\tau/t_1} \quad (4.4)$$

where A , B and t_1 are constants. These constants are related to the on- and off-times via the equations

$$\frac{\tau_{off}}{\tau_{on}} = \frac{B}{A} \quad (4.5)$$

and

$$\frac{1}{t_1} = \frac{1}{\tau_{on}} + \frac{1}{\tau_{off}}. \quad (4.6)$$

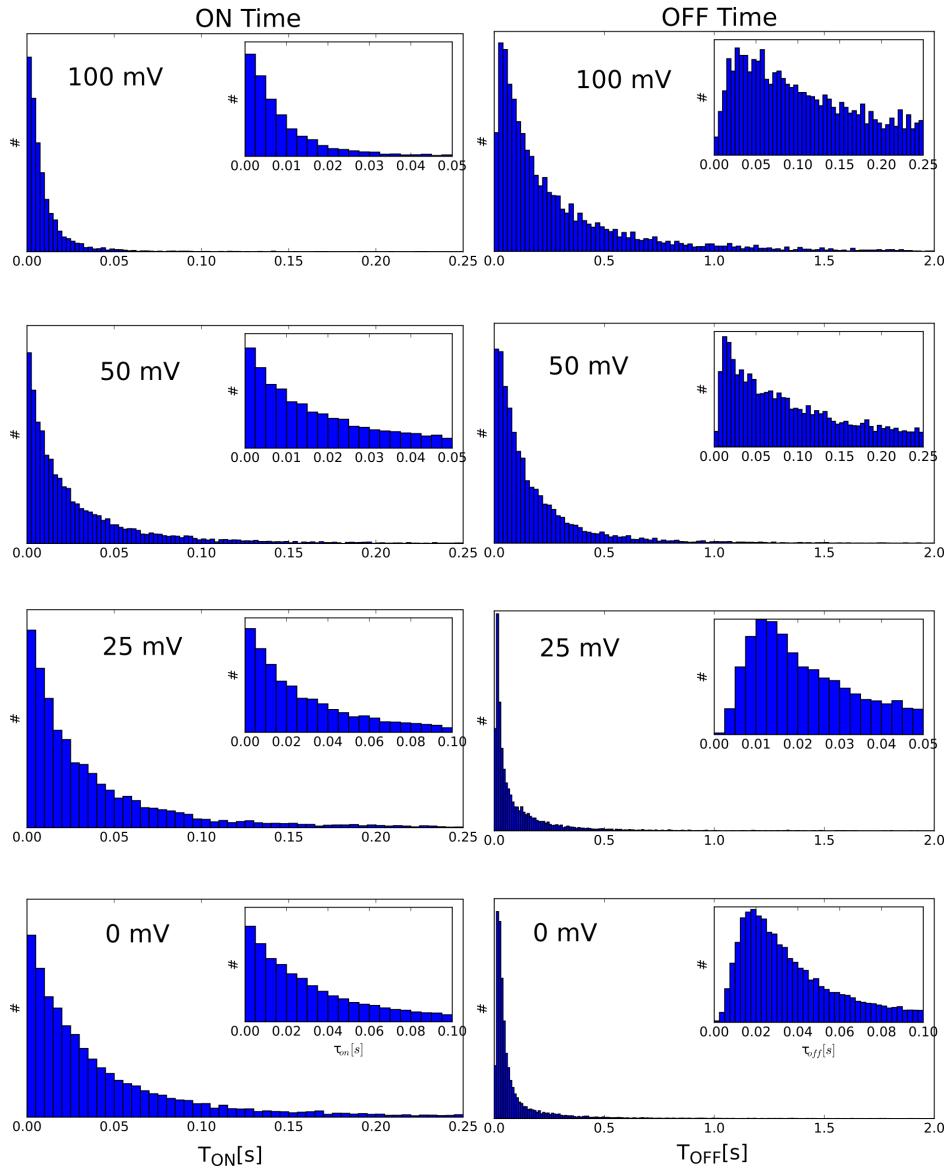

Figure 4.4: Histogram distribution τ_{on} and τ_{off} of CuAz at different potentials.

These formulas have been used in similar autocorrelation analysis ([21],[22]). When the potential reaches values of 40 mV and below, the interaction between the dye and the reduced ascorbate and ferricyanide becomes prominent and the fit of the autocorrelation consists of two exponentials. In contradiction to what one would expect, this is NOT simply a sum of two exponentials, such as

$$g(\tau) = A + B_1 e^{-\tau/t_1} + B_2 e^{-\tau/t_2}. \quad (4.7)$$

The latter formula is valid if t_1 and t_2 are not correlated or if $t_1 \gg t_2$ ($t_1 \ll t_2$). With $t_1(t_2)$ belonging to the redox switching and $t_2(t_1)$ to the blinking of the dye, this is clearly correlated. As mentioned before, for potentials below 40 mV the blinking of the dye becomes more prominent and the difference between t_1 and t_2 is within a few orders of magnitude. The mentioned sum of exponentials is for this case more complicated and up to this point in time the exact form of this exponent is not known. To keep things simple, only the (single exponential) autocorrelation for potentials higher than 40 mV, as described by equation 4.4, will be discussed in this thesis.

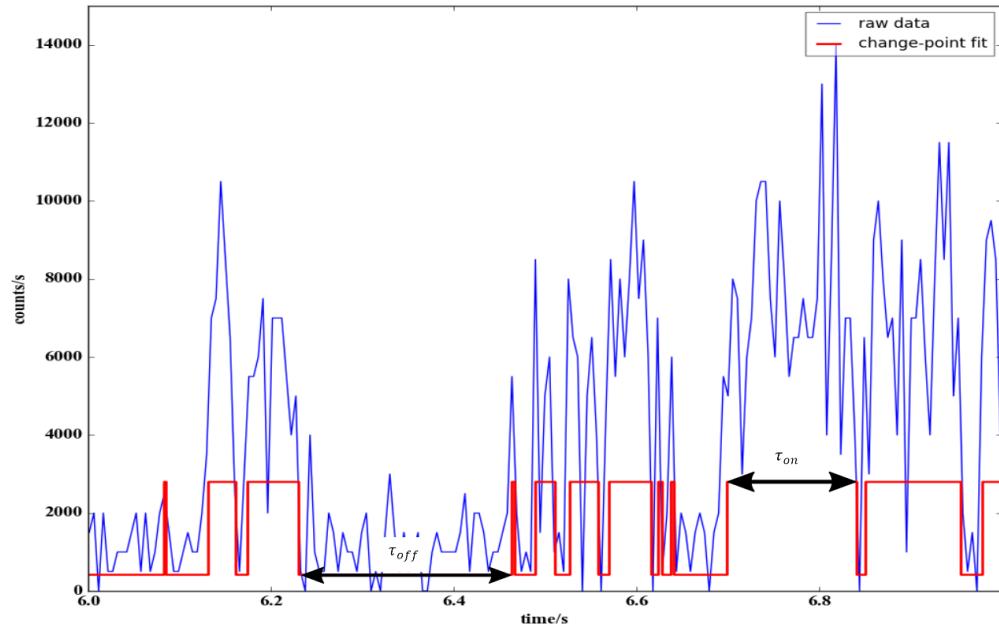

Figure 4.5: Same timetrace as Figure 4.2 but a smaller range. In red is plotted the calculated intensity jumps according to the program written by Lucas P. Watkins and Haw Yang. The time when the intensity is low is referred to as the τ_{off} and the time the molecules intensity is high is the τ_{on} .

4.0.3 Distribution midpoint potential CuAz

To give the redox switching of the CuAz a more quantitatively meaning, the average τ_{on} ($\bar{\tau}_{on}$) and average τ_{off} ($\bar{\tau}_{off}$) can be related to the Nernst

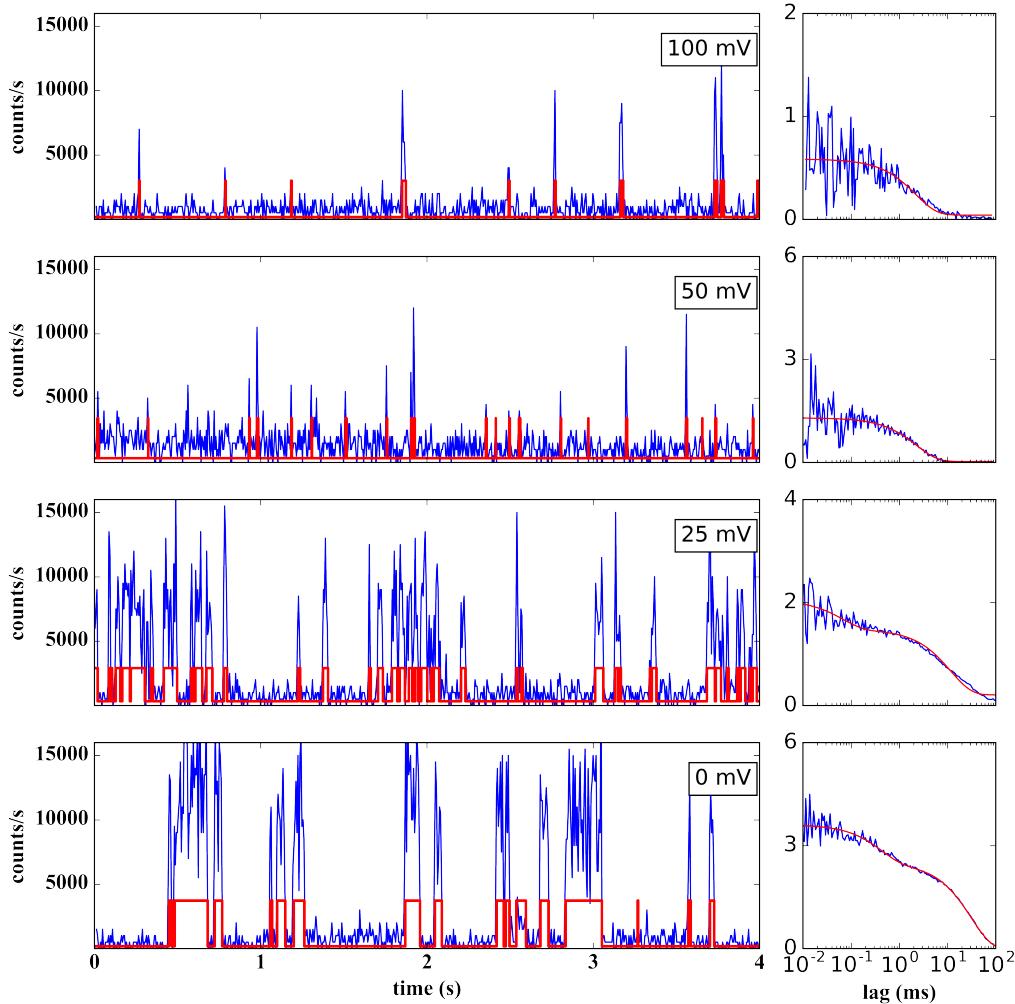

Figure 4.6: Timetraces together with their autocorrelation of the same CuAz molecule under different potentials. A clear difference between τ_{on} and τ_{off} under different potentials is visible: shorter τ_{on} for higher oxidizing potentials, longer τ_{on} for reducing lower potentials. For potentials below 40 mV this pattern gets disturbed due to blinking of the ATTO 655.

equation since the switching is due to the redox reaction of CuAz. Rewriting equation 2.6 to

$$E = E_0 + \frac{k_B T}{ne} \ln \left(\frac{\bar{\tau}_{off}}{\bar{\tau}_{on}} \right) \quad (4.8)$$

the average on- and off-times can be related to the potential applied. Rewriting equation 4.8 leads to

$$\frac{\bar{\tau}_{off}}{\bar{\tau}_{on}} = \exp \left(\frac{E_0 - E}{0.059} \right). \quad (4.9)$$

A fit through the ratio of the $\frac{\bar{\tau}_{off}}{\bar{\tau}_{on}}$ and the applied potential E will lead to the midpoint potential E_0 of the protein. To extract the midpoint potential, two different methods are combined. The first method is the direct calculation of the on- and off-times from the timetraces with the use of the changepoint program written by Lucas P. Watkins and Haw Yang. The second method uses exclusively the autocorrelation to find the ratio of $\frac{\bar{\tau}_{off}}{\bar{\tau}_{on}}$ for any given potential. As discussed, only the potentials between 40 mV and 100 mV are included. Another requirement is the activity of the molecule. Only CuAz that is still active after at least four different potentials has been taken in consideration. Using 42 different CuAz molecules, the distribution of 42 molecules is plotted in Figure 4.7 together with their Gaussian fit. The distribution acquired directly from the timetraces has a mean of 0.59 mV and a full width at half maximum (FWHM) of 24.58 mV. When the distribution is acquired from the autocorrelation, the mean is 5.12 mV and the FWHM is 24.95 mV. Such distribution of the midpoint potentials of CuAz has been reported earlier [23] where the midpoint potential was found to vary by tens of millivolts across the electrode surface. The mean of the distributions differ from the literature (around 25 mV). This kind of difference in midpoint potentials has been reported by other similar experiments [24] and explained due to strong irradiation. Single molecules show lower mid-point potential when excited at higher intensity. This aspect has to be confirmed by further research in this specific case however.

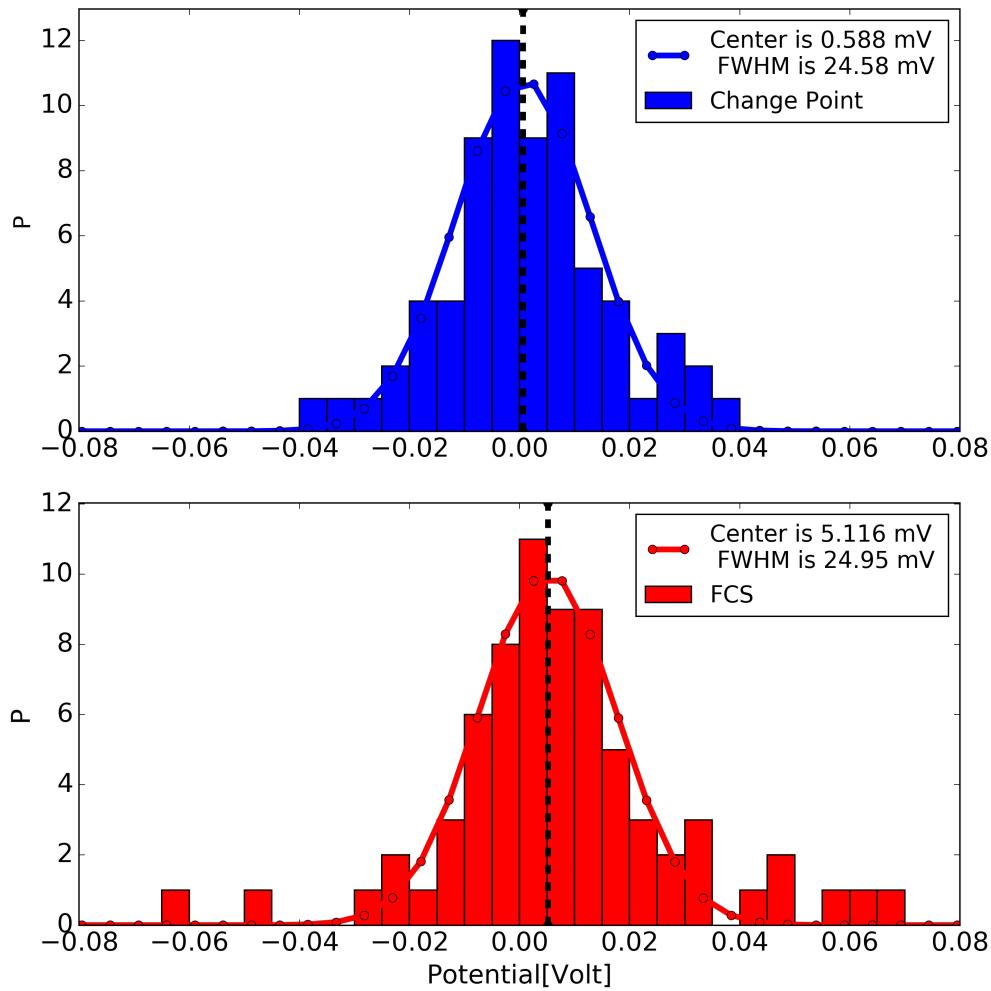

Figure 4.7: Histogram and distribution of the midpoint potential of CuAz. Top: the distribution of the midpoint potential of CuAz acquired directly from the timetraces fitted with a Gaussian function. The mean is 0.59 mV and the FWHM is 24.58 mV. Bottom: the distribution acquired from the auto correlation. The mean is 5.12 mV and the FWHM is 24.95 mV.
